Abstract

It is shown that with allowance for nonadditivity the (canonical) distribution for a black hole transforms to a (microcanonical) distribution which depends on nonadditive integrals of the motion and represents a nonlinear function of energy - the square of black hole mass. From a comparison with the standard microcanonical distribution it is found that the statistical weight of black hole should be proportional to the black hole area. A definition of the black hole entropy consistent with the statistical weight is proposed.

The statistical interpretation of the thermodynamical entropy of a black hole

$$S_{BH} = \frac{A}{4l_P^2}, \quad (1)$$

where A is the area of black hole horizon and l_P the Planck length, is still a central problem in black hole physics. In statistical mechanics all properties of a system are encoded in its distribution function [1]. For a classical system the distribution function $\rho(q_i, p_i)$ determines the probability to find the coordinates q_i and momenta p_i of the system in intervals between q_i , p_i and $q_i + dq_i$, $p_i + dp_i$. For a quantum system the distribution function w_n determines the probability to find the system in a state with energy E_n . The determination of this function for a system is the fundamental problem of statistical physics. The form of the function is usually postulated; its

justification lies in the agreement between results derived from it and the thermodynamic properties of a system.

There exist three main forms of the distribution function which play an important part in statistical physics, corresponding in turn to a microcanonical ensemble, whose elements have the same energy, volume and number of particles, a canonical ensemble, with elements of same temperature, volume and number of particles and a grand canonical ensemble, a set of elements having equal temperature, volumes and chemical potentials. The canonical ensemble is related to the microcanonical ensemble in that a large system with finite interactions can be subdivided into a relatively small independent subsystems; the system as a whole is isolated and is described by a microcanonical ensemble. In turn, the canonical ensemble can be viewed as a "microcanonical" with respect to grand canonical¹. Although the concept of the distribution function is successfully used in statistical physics, the important fact is that arguments used in deriving the distribution function are based on the additivity properties of ordinary matter and, more fundamentally, on the possibility of describing a given system as made up of independent subsystems. However the black holes are not conventional systems: they are nonadditive. The main reason for this depart from the conventional systems lies in the long-range behavior of gravitational forces. As is well known, the fact that the gravitational energy is nonadditive appears already in Newtonian gravity. In general relativity a local definition of mass is not possible; the ADM and Komar definitions of mass demonstrate this very clear. Moreover the black hole entropy (1) goes as the square of mass M^2 in a sharp contrast with the additive character of entropy in ordinary thermodynamics. It is clear that this aspect of nonadditivity can not be ignored in deriving the distribution function for a black hole as well as in deriving the black hole entropy. But this aspect has not yet received attention in the literature.

In this paper I suggest the forms of distribution function and entropy for a Schwarzschild black hole making allowance of nonadditivity.

We begin with conventional systems. The standard determination of the distribution function for them is given in detail by Landau and Lifshitz [1]. Following Landau and Lifshitz consider an ordinary isolated system

¹In this paper we use only the microcanonical and canonical ensembles. For this reason we shall not discuss the interesting approach of Gour (treating the Schwarzschild black hole as a grand canonical ensemble) and the reader is referred to the original paper [2].

consisting of quasi-isolated subsystems in thermal equilibrium. According to Liouville's theorem the distribution function of isolated system is an integral of the motion. Due to the statistical independence of subsystems and, as a consequence, multiplicativity of their distribution functions, the logarithm of the distribution function must be not merely an integral of the motion, but an additive integral of the motion. There exist only seven independent additive integrals of the motion: the energy, the three components of the momentum vector and the three components of the angular momentum vector. It can be shown that the statistical state of a system executing a given motion depends only on its energy. Thus we can deduce that the logarithm of the distribution function must be a linear function of its energy of the form

$$\ln w_n^{(a)} = \alpha^{(a)} + \beta E_n^{(a)}, \quad (2)$$

with constant coefficients α and β , of which α is the normalization constant and β must be the same for all subsystems in a given isolated system; the suffix "a" refers to the subsystem a . Note that assuming another dependence $\ln w$ on E we may not obtain an additive function on the right side of (2); for example, E^2 is already a nonadditive function. Since the values of nonadditive integrals of the motion do not affect the statistical properties of ordinary isolated system, these properties can be described by any function which depends only on the values of the additive integrals of the motion for the system and which satisfies Liouville's theorem. The simplest such function is

$$dw = \text{const} \times \delta(E - E_0) \prod_a d\Gamma_a, \quad (3)$$

where the number of states of the whole system $d\Gamma$ is a product $d\Gamma = \prod_a d\Gamma_a$ of the numbers $d\Gamma_a$ of the subsystems (such that the sum of the energies of the subsystems lies in the interval of energy of the whole system dE). It defines the probability of finding the system in any of the $d\Gamma$ states; $d\Gamma$ plays a role analogous to the classical elementary volume $dq dp$. The factor *const* is the normalization constant, $\delta(E - E_0)$ the delta function. The distribution (3) is called microcanonical. Note that (2) is nothing but the canonical distribution if we identify $\beta = -1/T$, $\alpha = F/T$, F being the free energy and T the temperature of the system.

As is easily seen, the statistical independence and additivity play a crucial role in deriving the distribution function for the conventional systems. Now

consider the black holes. An isolated black hole is not stable in empty flat space. So it is helpful to begin by placing black holes in an appropriate "box" so that a stable equilibrium configuration of black holes and their radiation can exist. As is well known from the thermodynamical considerations [3], at sufficiently high energies the entropy of such an isolated system is dominated by a single black hole; this corresponds to a microcanonical ensemble. As mentioned above, the black holes are not conventional systems: they possess the nonadditive properties. Because of the nonadditivity, the black holes can not be thought as made up of any independent subsystems. The presence of the logarithm in (2) is just determined by the statistical independence of the subsystems. Therefore, if we want to establish the distribution function for the black holes, we should remove the restrictions of the statistical independence and additivity of integrals of the motion for the subsystems of black hole. So dropping the logarithm and suffix "a" in (2) we obtain

$$w_n = f(E_n), \quad (4)$$

where $f(E_n)$ represents a nonadditive integral of the motion and is a non-linear function of the black hole energy. The simplest such function is the square of energy, $f(E) = \gamma E^2$. Note that as in ordinary statistics, the form of the distribution function must be regarded only as a postulate, to be justified solely on the basis of agreement of its predictions with the thermodynamical properties of black holes. Our considerations are intended to make it plausible, and nothing more. As a result, the (canonical) distribution for a subsystem (2) transforms to the (microcanonical) distribution for the whole system of the form

$$w_n = \gamma E_n^2, \quad (5)$$

where γ is a constant coefficient. Similarly dropping the product and suffix "a" in (3), we obtain

$$dw = \text{const} \times \delta(E - E_0) d\Gamma, \quad (6)$$

or after integration,

$$w = \text{const} \times \Delta\Gamma, \quad (7)$$

where $\Delta\Gamma$ is already the total number of states that accessible to the whole system in a given state. The functions (5) and (7) are obviously the same

and satisfy the same normalization condition $\sum_n w_n = 1$. So comparing (5) and (7) we get

$$\Delta\Gamma \propto M^2, \quad (8)$$

where the energy of black hole is identified with its ADM mass, M . Thus the statistical weight of black hole should be of the form

$$\Delta\Gamma = \frac{A}{\xi l_P^2}, \quad (9)$$

as is evident from dimensionality considerations. Here ξ is a new constant coefficient, $\xi > 1$.

Now we can define the entropy of black hole. The entropy plays a particularly fundamental role when the microcanonical ensemble is used. The entropy of a conventional system is given by the Boltzmann formula

$$S = \ln \Delta\Gamma. \quad (10)$$

So assuming the usual interpretation of entropy we would have to take a logarithm of (9). It appears that in this case the generalized second law of black hole thermodynamics would be violated [4]. The argument involves a well-known example with the collision of black holes: two identical black holes collide, merge, radiating gravitational wave energy, and form a third black hole. According to (10), the initial entropy of the system is

$$S_i = 2 \ln \Delta\Gamma_i = 2 \ln \left(\frac{A}{\xi l_P^2} \right). \quad (11)$$

On the one hand, the final entropy is bounded from above by

$$S_f = \ln \Gamma_f = \ln \left(\frac{4A}{\xi l_P^2} \right). \quad (12)$$

On the other hand, by virtue of the generalized second law it must be greater than initial entropy. So we have

$$2 \ln \left(\frac{A}{\xi l_P^2} \right) < S < \ln \left(\frac{4A}{\xi l_P^2} \right). \quad (13)$$

As is easily seen, these inequalities are satisfied only for $A < 4\xi l_P^2$. This means that the standard interpretation of the entropy in terms of the logarithm of $\Delta\Gamma$ violates the generalized second law. Thus we conclude that the statistical interpretation of the Bekenstein-Hawking entropy is correct only if log is deleted from the Boltzmann formula (10), that is, the black hole entropy should be proportional to the number of states,

$$S_{BH} \sim \Delta\Gamma. \quad (14)$$

In [4] a new statistical interpretation of the black hole entropy was suggested which does not use the properties of additivity and statistical independence. Namely, in [4] it was shown that the black hole entropy is of the form

$$S_{BH} = 2\pi\Delta\Gamma, \quad (15)$$

that is, in contrast to the entropy of ordinary matter, without the logarithm, and the number of microstates for a given area is $\Delta\Gamma = A/8\pi l_P^2$. This agrees with our form of the distribution function so we can identify $\xi = 8\pi$ in (9). Since our distribution is determined by the nonadditive integral of the motion (5), we consider the microcanonical entropy S_{BH} with fixed area rather than fixed energy.

As is well known, a description of a black hole via a thermal ensemble is inappropriate. Thermodynamically the heat capacity of a Schwarzschild black hole is negative, so it cannot come to equilibrium with an infinite heat bath. From the point of view of statistical physics this could be explained as follows. According to the canonical distribution, the probability p_i of a system being in a state of energy E_i is proportional to the Boltzmann factor,

$$p_i \sim \Delta\Gamma_i \exp\left(-\frac{E_i}{T}\right), \quad (16)$$

where T is the temperature of the system. Assuming the usual interpretation of entropy (10), the statistical weight of black hole should grow with M as

$$\exp(4\pi GM^2). \quad (17)$$

In that case, the total probability diverges. However, in the case where the entropy is given by (15), the statistical weight grows as

$$2GM^2, \quad (18)$$

and the probability can converge. So, it seems that the usual value of the statistical weight (17) better explains the breakdown of the canonical ensemble for black holes than suggested (18). But this is not the case. First, it is clear that an infinite heat bath is gravitationally unstable. On the other hand, there is always a size of bath at which the interaction energy between the members of ensemble is not negligible. In both cases the canonical distribution is not applicable. Secondly, a black hole possesses a very special property which singles it out; namely, its size and temperature are not independent parameters. As a result, the temperature of black hole does not remain constant, contrary to the definition of canonical ensemble. Note that the ordinary self-gravitating systems, for example, stars and galaxies, also have the negative heat capacity. And although their statistical weights grow not so fast as (17), they can not be in a thermal equilibrium with a heat bath. Thus the apparent divergence of canonical distribution, in the case where the statistical weight grows as (17), cannot be an evidence in support of the usual interpretation of black hole entropy.
